

A quick writeup about the model

The core of this model is an RBFNN that can predict a future datapoint. For year x , this is done to use all the datapoints in x to predict a value in year $x+1$. This is done for each datapoint to fully generate the following year. Then the already well-trained model for GDP/growth prediction is used to predict the final y-axis value (gdp and growth respectively in files 1 and 2). Each time this is done, the prediction model is retrained on the previous data.

Instructions: Here, the data provided in the source code is used to first train the model. This trained version is then stored as an RBFNN object and used later. Currently, my code retrains the model for each evolution of the prediction year, but this is not needed and this line of the code can be commented out. Essentially, training will allow us to determine the FutureModels and MainModel and GrowthModel and these will remain fixed by commenting that line of code. Then, the GDP can be forecast using the provided function, which will give out a tuple in the same format as the input. The respective column will be the GDP and Growth respectively.
